Binary powder mixtures, consisting of large and small diameter particles, are used in electrophotographic (EP) printing devices where control of the relationship between the flow properties and mixing ratio is of great importance. In this study, we have experimentally investigated the bulk flow properties (i.e., bulk cohesion and internal friction) of large-and-small fine binary powder mixtures (size ratio: \(d_l/d_s = 9.17\)) as a function of the volume ratio of the smaller component, \(x_s\). Using polymer spheres as the smaller constituents, whose bulk cohesion was controlled by surface additives, we have obtained systematic data on the effect of the smaller constituent. A semi-empirical model was then developed, in which the total bulk cohesion is expressed as a linear superposition of the numbers of the three types of particle–particle contacts (i.e., large–large, small–small, and large–small) involved in the shear motion. The model successfully reproduced the experimental data after fitting appropriate values of a parameter representing the adhesion at large–small particle contacts. The rapid increase of the number of particles involved in the shear motion as a function of \(x_s\) near \(x_s = 0\) was also considered in the model. The model clarifies the contributions of the three types of particle–particle contacts to the total bulk flow properties. The effect of large–small particle contacts on the bulk cohesion was observed for almost all values of \(x_s\). The value of \(x_s\) at which the contribution of large–small particle contacts in the total bulk cohesion becomes a maximum shifted in the direction of larger \(x_s\) when a less cohesive small powder was used. This also resulted in a shift of \(x_s\) at which the internal friction reached a minimum.

1. Introduction

Two-component dry powder developers, comprised of binary mixtures of small and large particles, have been used in electrophotographic (EP) printing devices such as laser printers and photocopier machines for more than half a decade [1]. Two-component developers are composed of toner – resin particles with a diameter of 5–10 μm functioning as colouring materials – and carrier particles, usually made of magnetic materials with a mean diameter of 50–100 μm, which promote the electrostatic charging of the toner particles and carry the toners onto the latent images. Inside the EP printing device, a mixture of toner and carrier particles is intermittently circulated under applied shear and normal stresses in the range of 1–10 kPa. Since the flow behaviour of the developer affects the image quality, it is crucial to control their flow properties appropriately [2,3].

Whilst many of the factors affecting the flow properties of two-component developers, such as particle size and shape distributions, composition, and mechanical characteristics, do not change significantly during normal operation of EP printing devices, the mixing ratio, or compositional balance, of the constituent particles is one of the most important variables to control in the process [1]. Therefore, understanding the relationship between the flow properties and mixing ratio of binary powder mixtures is of great importance for proper control of the flow behaviour of EP two-component developers.

In this study, we present a semi-empirical model which describes the relationship between the bulk flow properties of large-and-small dry fine binary powder mixtures and the ratio of the component powders, incorporating the contacts between the constituent particles. Specifically, the model estimates the number of particle contacts involved in the incipient flow motion, taking into account the change in the width of the incipient shear zone, and links these to changes in the flow properties. In fact, an understanding of the fundamental physics connecting changes in the particle contact network and width of the incipient shear zone to the onset of incipient flow is of wide benefit to a range of granular systems beyond EP printing devices such as the processes of powder materials in pharmaceutical and food industries.

However, despite its importance, the number of fundamental studies exploring the bulk flow properties of large- and small binary powder mixtures in terms of the mixing ratio of the constituent particles is still limited. There exists some experimental research investigating the relationship between the bulk flow properties and mixing ratio of the binary powder mixtures [4–6], but the analyses of the mechanisms were rather qualitative. Computational modelling studies also exist
(e.g. Ref. [7,8]) but the results are again rather limited due to the high complexity of such systems, although this might potentially be a useful approach with further improvements of computational speed and modelling techniques in the near future. The current study aims to address the gap between experimental measurements and numerical simulations towards the ultimate goal of an improved understanding of their linkage.

In this study, we firstly investigated the bulk flow properties of fine binary powder mixtures experimentally. We used fine powders to construct model systems of two-component developers used in EP printing devices, thus eliminating any confounding factors such as the varying geometric shapes of the constituent powder particles and unknown surface treatments. In a previous study, we successfully performed systematic measurements by using commercially-available toner powders as the smaller constituent of the mixtures [2]. However, in present work, in order to develop a model which correctly describes the adhesive property between the constituent particles, we utilised spherical polymer powders as the smaller constituents whose bulk cohesions were systematically controlled.

Then, a semi-empirical model, which explains the bulk flow properties of the binary powder mixtures in terms of the contacts of the constituent particles, was developed by estimating the number of particle contacts at the point of incipient flow. There exist some studies discussing the particle packing of two- or multi-component powder mixtures from the microscopic viewpoint, relating the bulk packing density to the number of particle contacts (i.e. coordination number), including experimental measurements [9,10], analytical modelling [11–18], and computational simulations [17]. In this study, a geometrical model proposed by Suzuki et al. [12–14], in which the coordination number of the constituent particles in the binary powder mixtures is calculated from the bulk density (or voidage) of the systems, was used for the estimation of the numbers of particle contacts in the system. The experimental data were then analysed further using the proposed model to determine its validity.

The remainder of this article is structured as follows: after describing the experimental methods and materials in Section 2, the results of the measurement of the powder packing structures and flow properties such as bulk cohesion and internal friction of the binary powder mixtures are presented in Sections 3 and 4, respectively. A model equation to relate the particle contacts in the powder mixtures and their flow properties is then introduced in Section 5, and further analyses based on the model are given in Section 6. We conclude by summarising the achievements in Section 7.

2. Experimental methods and materials

Several types of powders composed of smaller particles with different bulk cohesions were prepared for the purpose of developing a model describing the adhesive property between the constituent particles properly. Binary powder mixtures were then made using each small–particle powder together with a large–particle powder, in which the mixing ratio was systematically changed, and the incipient flow properties of the powder mixtures were measured under the same experimental conditions. The details of the measurement methods of the flow properties, as well as the powder materials used for the binary mixtures, are described in the remainder of this section.

2.1. Measurement of flow properties

The incipient flow properties of the powder samples were evaluated using a ring shear tester (RST) RST-XS (Dietmex Schulze, Germany). The fundamental principles of shear testing, as well as a description of the RST equipment, are summarised elsewhere in various textbooks and papers (e.g. Refs. [18,19]).

The series of measurements were conducted under the same experimental conditions as Ref. [2]. The powder sample was at first placed into the ring-shaped shear cell of height 13 mm, inner and outer diameters of 32 and 64 mm, respectively, and the lid with radial vanes of height 3 mm distributed every 22.5° on its lower surface, was loaded onto the sample. In each measurement, the incipient shear stresses, , were measured under normal stresses of 0.6, 1.1 and 1.6 kPa after pre-shear consolidation with a normal stress of 2.0 kPa.

In all cases, the obtained data showed good linearity (correlation coefficients, R², of the linear fitting were greater than 0.994). Based on this, two parameters representing major incipient flow properties, bulk cohesion and internal friction, were obtained from the yield locus, a line fitted to the three measured (, ) points in the plane (i.e. a Mohr–Coulomb yield locus) and expressed by the following equation:

\[
\tau = \sigma \cdot \tan \phi_{\text{lin}} + \tau_c. \tag{1}
\]

In Eq. (1), the intercept of the yield locus, represents the bulk cohesive property of the powder sample and is called ‘bulk cohesion’. Also, the angle of the slope of the yield locus, , is a measure of the internal friction of the powder sample and is termed the ‘linearised friction angle (LFA)’.

The bulk structure of every powder sample was also evaluated from the voidage, which represents the volume ratio of the voids in the total volume of powder system. The value of was calculated from the bulk density of the powder, , obtained in the RST measurement, particle densities of the large and small components: and , and the volume ratio of the small powder, , by using the following relationship:

\[
e = 1 - \frac{\rho_b}{\rho_p (1 - x_s) + \rho_p x_s}. \tag{2}
\]

Each measurement was carried out under standard conditions of 21 ± 2 °C and 38–55% relative humidity (RH). The fluctuations of room temperature and RH did not affect the results.

2.2. Powder materials

Glass ballotini (Ballotini solid soda glass balls, diameter 40–70 μm, Sigmund Lindner, Germany) of the same type as in a previous study [2] were used as the larger component in the binary mixtures. Before being used for the flow measurement, the ballotini powder was washed using liquid detergent and rinsed thoroughly in distilled water in order to eliminate fine impurities on the particle surface. After being dried in the cabinet with an internal temperature of approximately 80 °C for at least 8 h, it was then sieved using a set of three nested sieves with different mesh sizes (38, 90 and 100 μm from bottom) in order to obtain a sufficiently uniform and narrow size distribution. Only the powder remaining on the 38 μm sieve was used for the evaluation of the flow properties. For the smaller component of the binary mixtures, a polymer powder composed of poly(styrene-co-divinylbenzene) (PS-DVB) microspheres (Sigma-Aldrich, USA) was used without pre-treatment process.

The cumulative size distributions of the powders obtained by image analysis are shown in Fig. 1, together with representative SEM images of each type of particles (SEM: JEOL 6340 F FEG–SEM). Under the SEM, the constituent particles of both glass ballotini and PS-DVB powders appeared almost spherical, and also the surface of the glass ballotini was confirmed to be almost smooth and impurity-free. The size parameters such as volume mean diameter, , and geometric standard deviation, , of each powder were obtained by fitting a log-normal function, which closely followed the cumulative size distribution of each powder. The particle density of each powder was measured by a gas pycnometer (Accupyc 1330, Micromeritics, USA). The values of size parameters and particle density are summarised in Table 1.
2.3. Surface modification of PS-DVB powder

For the control of the cohesive property of the PS-DVB powder, a dry coating technique, in which nanometre-sized materials are added to the surface of host particles as ‘flow regulators’ or ‘surface additives’, was adopted. As discussed in a previous study, the cohesive property of the PS-DVB powders can be systematically controlled over a wide range by changing the type and quantity of silica nanoparticles applied as surface additives. Such surface additives have only a small effect on the internal friction [20]. In this study, 12 nm hydrophobic silica nanoparticles, Aerosil® R805 (Evonik Industries, Germany), were chosen as the surface additives for the PS-DVB powder particles. The BET surface area of the silica nanoparticles provided by the supplier was 150 ± 25 m² g⁻¹.

Four types of surface-modified PS-DVB powders covered with different quantities of 12 nm hydrophobic silica nanoparticles: 1, 5, 10, and 100% theoretical surface coverage (TSC) were prepared based on the results in Ref. [20], in which the bulk cohesion of the PS-DVB powders decreased with increase of the quantity of silica nanoparticles in the expected range of 90–380 Pa. The TSC was calculated from the surface area of PS-DVB microspheres and total projected area of the silica nanoparticles on the surface of the PS-DVB particles, when all of the silica nanoparticles are considered to be existing as primary particles, using the mean diameters of their primary particles. For ease of reference, the surface-modified PS-DVB powders are termed as PS-DVB(χ) where χ represents the TSC of the 12 nm hydrophobic silica nanoparticles as a percentage (i.e. 1, 5, 10 or 100%). For instance, PS-DVB(10) denotes a PS-DVB powder covered with 10% TSC of silica.

In order to coat the PS-DVB powders with surface additives, the same process was employed as described in Ref. [23]. A commercially available mixer, composed of a plastic container with a capacity of 400 ml (diameter 80 mm) and two stainless steel blades (almost isosceles triangles, with 15 mm base and 36 mm height, rotating at approximately 18,000 rpm), was used for the addition of the silica nanoparticles to the surface of the PS-DVB particles. In each case, 30 g of the PS-DVB powder and an appropriate quantity of silica nanoparticles to achieve the desired TSC were mixed together for 120 s. Fig. 2 shows the magnified SEM images of the particle surface of each surface-modified PS-DVB particles. In each case, the surface-modified PS-DVB powder was stored for at least 8 h before being mixed with glass ballotini in order to eliminate the possible effect of electrostatic charge due to friction between particles or the wall of the bottle during the mixing process.

The incipient flow properties and voidage of these surface-modified PS-DVB powders were measured prior to the evaluation of binary powder mixtures as summarised in Table 3. The bulk cohesion of the surface-modified PS-DVB powder was systematically decreased by up to approximately 270 Pa by increasing the quantity of the silica nanoparticles applied to the surface of the PS-DVB particles from 1 to 100% TSC. The values of the LFA were not significantly affected by changing the quantity of silica nanoparticles applied; they were identical to within 5%. These observations correspond to the facts reported in Ref. [20] that increasing the TSC of surface additives systematically decreases the bulk cohesion of the host particles with a small effect on LFA. A linear correlation was found between the bulk cohesive properties of the surface-modified PS-DVB powders and their voidage, as shown in Fig. 3; the less cohesive they are, the more densely the powders can be compacted.

2.4. Preparation of binary powder mixtures

Binary powder mixtures composed of glass ballotini and surface-modified PS-DVB powders were prepared in varying compositions for the evaluation of their flow properties. The powder mixtures were mixed in a 200 ml plastic bottle by shaking it approximately 250 times per minute for 2 min with amplitude of approximately 20 cm, as in Ref. [2]. Each mixture was confirmed to be sufficiently well mixed without apparent segregation from the fact that the colour of the sample was uniform throughout. Each mixture was stored for an extended period (at least 12 h) before being placed in the RST in order to eliminate the possible effects of electrostatic charging.

3. Packing structure of binary powder mixtures

The voidage, ϵ, of the binary mixtures composed of the glass ballotini and surface-modified PS-DVB powders is shown in Fig. 4 as a function of the volume ratio of the PS-DVB powder, xₚ (on a logarithmic scale). A common trend was observed for all the data: the voidage shows a ‘funnel shape’ curve, obtaining a minimum value at approximately xₚ = 0.4 in each case. As seen from Fig. 4, the powder mixtures were compacted more densely by using less cohesive PS-DVB powders for the same xₚ over the entire range of xₚ.

There exist a number of numerical models for binary powder mixtures illustrating the relationship between the packing density and ratio of the component powders, as summarised elsewhere (e.g. Refs. [2,21,22]). Among them, the model proposed by Westman
describes the relationship in a relatively simple quadratic equation expressed as follows:

\[
\left(\frac{V-V_l x_l}{V_s}\right)^2 + 2G \left(\frac{V-V_l x_l}{V_s} - \frac{V-V_l x_s}{V_l - 1}\right) + \left(\frac{V-V_l x_s}{V_l - 1}\right)^2 = 1, \tag{3}
\]

where \(V\) is the specific volume of the powder mixture (equivalent to the reciprocal of \(1 - \varepsilon\)), \(V_l\) and \(V_s\) are the partial specific volumes of large and small particles corresponding to the specific volumes of the large and small powders alone, and \(x_l\) and \(x_s\) are the volume ratios of the large and small powders, respectively (\(x_l = 1 - x_s\)). In the original Westman model [23] or its modified versions [22,24], which show good agreement with the experimental results for non-cohesive powder mixtures, the parameter \(G\) is a function of size ratio of the two component powder particles. For fine cohesive powders, \(G\) can be regarded as an index representing how easily the binary mixture can be compacted, as mentioned in a previous study [2]. Since the measured values of the voidage in the small \(x_s\) region, in each case, show a more rapid decrease with increase of the PS-DVB powder than the model predicts, Eq. (3) was fitted to the measured voidage for \(x_s \geq 0.4\) by using \(G\) as a variable parameter. The solid lines in Fig. 4 are the results of these fittings, and the values of \(G\) for each line are listed in Table 4. These values are used in Section 6 to discuss the relationship of the packing structure with adhesive properties of the constituent particles.

As seen in Fig. 4, the measured voidage shows some significant deviation from the values predicted by Eq. (3) in the direction of smaller \(\varepsilon\) for the low \(x_s\) region (\(x_s < 0.1–0.2\)). According to the model, the smaller particles are expected to fill in the voids between the larger particles with little disruption of the bulk packing structure of the larger particles in the low \(x_s\) region when the size ratio of large and small constituents, \(r = d_l/d_s\), is sufficiently large, typically nearly 10 or larger [22–24]. The value of \(r\) is 9.17 in this case, which seems to almost meet this condition. Based on these facts, the deviation of the measured voidage from the

![Fig. 2. SEM images of the surface-modified PS-DVB particles coated with different amounts of 12 nm hydrophobic silica nanoparticles: (a) PS-DVB(1), (b) PS-DVB(5), (c) PS-DVB(10), and (d) PS-DVB(100), where PS-DVB(\(\chi\)) represents the theoretical surface coverage (TSC) of nanoparticles as a percentage.](image)

![Fig. 3. Relationship between voidage and bulk cohesion of the surface-modified PS-DVB powders.](image)
model observed in small $x_s$ region seems to indicate that the PS-DVB particles added to the glass ballotini powder disrupt the bulk structure of the pure glass ballotini and allow the formation of a denser packing structure. Fig. 4 shows that the PS-DVB particles with a larger quantity of 12 nm hydrophobic silica nanoparticles disrupt the bulk structure of the glass ballotini to a greater extent, forming denser packing structures according to the magnitude of discrepancies between the calculated (lines) and experimental (squares) values.

4. Flow properties of binary powder mixtures

4.1. Bulk cohesion

In a previous study [2], the bulk cohesion of glass ballotini was reduced by the addition of minute amounts of toner particles ($x_c = 0.002-0.005$), which was attributed to the fact that the toner particles disrupted direct contacts between the glass ballotini particles, thus reducing the van der Waals attractive force between them. However, in this study, the bulk cohesion in general increased from that of the pure glass ballotini on the addition of a small quantity of surface-modified PS-DVB particles, as seen in Fig. 5(a), which shows the bulk cohesion, $\tau_b$, of the binary powder mixtures of glass ballotini and surface-modified PS-DVB as a function of the volume ratio of the PS-DVB powder. This seems to suggest that the effect of the contacts between glass ballotini and surface-modified PS-DVB particles should also be taken into account. As more PS-DVB particles were added, the bulk cohesion decreased until $x_s$ reached approximately 0.05. Once $x_s$ exceeded 0.07–0.1, the bulk cohesion of the powder mixtures increased rapidly with increasing the PS-DVB particles. The values of the bulk cohesion converged on that of the surface-modified PS-DVB powder after reaching a peak at $x_s = 0.4$–0.8.

Furthermore, the bulk cohesion of the powder mixtures containing a less cohesive PS-DVB powder became smaller at the same $x_s$ over the entire range, as seen in Fig. 5(a). In fact, when the bulk cohesion is compared with the voidage, shown in Fig. 4, these parameters seem to have a correlation with each other; the denser the mixture, the higher the bulk cohesion, which seems to suggest a strong effect of the bulk flow properties of the powder mixtures on the packing structure of the particles. Their relationship is discussed in more detail in Section 6.

4.2. Internal friction

The relationship between the linearised friction angle (LFA) of the binary powder mixtures, $\phi_{lin}$, and volume ratio of the smaller component, $x_s$, is shown in Fig. 5(b). In general, the dependence of the LFA on $x_s$ displayed a funnel-shape curve in each case, having a minimum at $x_s = 0.1$–0.3, depending on the quantity of the silica nanoparticles added to the surface of the PS-DVB particles. In each case, the LFA of the powder mixtures was almost constant, or showed a slight decrease at $x_s = 0.05$–0.07, and then decreased rapidly to the minimum point with increasing $x_s$. In more detail, the LFA of the mixture composed of the surface-modified PS-DVB powder with a smaller quantity of silica nanoparticles (i.e. more cohesive PS-DVB powder) started decreasing rapidly at smaller values of $x_s$. The values of $x_s$ where the LFA reached the minimum, $x_s(\phi_{lin,min})$, also showed a systematic trend; the more cohesive the surface-modified PS-DVB, the smaller the value of $x_s(\phi_{lin,min})$. Furthermore, the minimum values of the LFA, $\phi_{lin,min}$, became smaller as a less cohesive surface-modified PS-DVB was used in the mixture. This seems to reflect that the more 12 nm hydrophobic silica nanoparticles...
that cover the surface of PS-DVB particles, the lower the friction between the surface-modified PS-DVB particles and glass ballotini becomes. Once the LFA reached a minimum at $x_s (Q_{\text{inc}, \text{min}})$, it increased with further increase of $x_s$ and converged on the LFA of the surface-modified PS-DVB powders in each case. Further discussion in terms of the relationship with particle contacts is given in Section 6.

### 5. Model relating flow properties and particle contacts

In this section, we develop a semi-empirical model to relate one of the flow properties of the binary powder mixtures, bulk cohesion $\tau_b$ to the packing structure in terms of the average number of particle contacts. In order to estimate the numbers of particle contacts in the powder mixtures, a model equation was applied based on the geometric analysis proposed by Suzuki et al.\[12–14\], which provides the average coordination number of the constituent particles of binary powder mixtures from their bulk structure (i.e. voidage). The details of the calculation of the coordination number with Suzuki’s model are provided in Appendix A.

Suzuki’s model takes into account the four cases of particle contact between the large (l) and small (s) particles in the mixture, corresponding to cases (i)–(iv) described in Appendix A. The average coordination number of the particles in a binary powder mixture, $N^c_{\text{all}}$, is the sum of the average numbers of the four types of particle contacts shown in the system, i.e.:

$$N^c_{\text{all}} = N^c_{\text{v, all}}(s) + N^c_{\text{v, all}}(l) + N^c_{\text{h, all}}(s) + N^c_{\text{h, all}}(l),$$

where $N^c_{\text{v, all}}$ is the sum of $N^c_{\text{v, all}}(s)$ and $N^c_{\text{v, all}}(l)$, representing the average number of contacts between large and small particles, corresponding to ballotini and PS-DVB, respectively.

When an incipient flow occurs in a powder, the incipient shear zone is usually thin [19] as shown in the two-dimensional schematic diagram in Fig. 6. In the case of single-component powders, the thickness of the incipient shear zone is equivalent to the length of approximately 10–20 particles, regardless of the particle sizes [25–27]. Here, let us assume that the bulk cohesion of binary powder mixtures can be expressed as a linear superposition of the numbers of three types of particle contacts existing in the incipient shear zone, i.e.:

$$\tau_b(x_s) = A \cdot N_{\text{v,sh}(s)}(x_s) + B \cdot N_{\text{v,sh}(l)}(x_s) + C \cdot N_{\text{h,sh}(l)}(x_s),$$

where $N_{\text{v,sh}(s)}$ and $N_{\text{v,sh}(l)}$ are the numbers of contacts of large–large, small–small, and large–small particles being involved in the shear motion or existing in the incipient shear zone respectively, and $A$, $B$, and $C$ are coefficients with units of stress. By introducing a dimensionless function, $f = f(x_s)$, which is proportional to the thickness of the incipient shear zone in the powder mixtures, the number of three types of particle contacts, ballotini–ballotini, (PS-DVB)–(PS-DVB), and ballotini–(PS-DVB), in the incipient shear zone can be expressed by the following equations:

$$N_{\text{v,sh}(s)} = f \cdot N_{\text{tot, s}},$$

$$N_{\text{v,sh}(l)} = f \cdot N_{\text{tot, l}},$$

$$N_{\text{h,sh}(l)} = f \cdot N_{\text{tot, pl}},$$

where $N_{\text{tot, s}}$ and $N_{\text{tot, l}}$ are the total numbers of all the particles in the powder mixture. Therefore, Eq. (5) can be rewritten as follows:

$$\tau_b(x_s) = f(x_s) \cdot N_{\text{tot, s}} \cdot \left[A' \cdot N_{\text{v,sh}(s)}(x_s) + B' \cdot N_{\text{v,sh}(l)}(x_s) + C' \cdot N_{\text{h,sh}(l)}(x_s)\right].$$

In Eq. (7), $f(x_s) \cdot N_{\text{tot, s}}$ is a relative measure of the number of total particles in the incipient shear zone. Since the thickness of the incipient shear zone is expected to be nearly proportional to (typically 10–20 times as large as) the diameter of particles in single component system according to the discussion in Ref. [23–25], that in large- and small-binary mixtures is also expected to be nearly proportional to the average diameter of the particle in the system as discussed in Ref. [8] in general. The average diameter, $d_{\text{ave}}$, is defined as follows:

$$d_{\text{ave}} = S_{1.1} \cdot d_l + S_{1.5} \cdot d_s,$$

where $S_{1.1}$ and $S_{1.5} = (1 - S_{3.0})$ are the number ratios of large and small particles, respectively. Fig. 7a shows the results of such a calculation of $d_{\text{ave}}, n_{\text{tot, l}}$ as a function of $x_s$, in which $d_{\text{ave}} \cdot n_{\text{tot, l}}$ shows an almost linear dependence on $x_s$ in each case. Taking into account the fact that $f(x_s)$ is nearly proportional to $d_{\text{ave}}$, the number of total particles in the incipient shear zone, i.e. $f(x_s) \cdot n_{\text{tot, s}}(x_s)$, is also assumed to increase almost linearly with increasing $x_s$ as shown by the dashed line in Fig. 7b. Also, it is reasonable to suppose that ratio of the incipient shear zone thickness of the pure larger powder (i.e. glass ballotini) to that of pure smaller powder (i.e. surface-modified PS-DVB) is equivalent to the ratio of their average diameters, i.e.:

$$f(1) \approx \frac{d_l}{d_s}.$$

In order to simplify the calculation, let $f(1)$ be equal to 1 and therefore $f(0) = d_l / d_s$. By calculating the gradient, $a$, in Fig. 7b, with $d_l / d_s$, $n_{\text{tot, l}}$ and $n_{\text{tot, s}}$, the function $f(x_s)$ is defined by the following equation:

$$f(x_s) = \frac{n_{\text{tot, s}}}{n_{\text{tot, l}}} \cdot \left[\frac{d_l / d_s}{n_{\text{tot, l}}} \cdot x_s + (d_l / d_s) \cdot n_{\text{tot, l}} / n_{\text{tot, s}}\right].$$

Now, the bulk cohesion of the powder mixtures can be calculated by assigning Eq. (10) to the function $f(x_s)$ in Eq. (7).

In Eq. (7), the value of $A'$ is specified by assigning $x_s = 0$ and applying $f = d_l / d_s$ as $A' = (\tau_{\text{cl}} / (N_{\text{tot, pl}} \cdot N_{\text{cl}})) / (d_l / d_s)$, where $\tau_{\text{cl}}$, $n_{\text{tot, pl}}$, and $N_{\text{cl}}$ are the bulk cohesion, number density, and coordination number of the glass ballotini, respectively. In the same manner, $B' = \tau_{\text{cs}} / (n_{\text{tot, s}} \cdot N_{\text{cs}})$.
and coordination number of the surface-modified powders were found between the results of calculation and experimental data in the small \( x_s \) region, although they agree well with each other when \( x_s \) exceeds 0.1. In fact, this discrepancy becomes more obvious as the bulk cohesion of the surface-modified PS-DVB powder becomes larger.

The bulk cohesion of the surface-modified PS-DVB particles depends on how much the surface additives on the PS-DVB particles disrupt their direct contacts; the more efficiently the additives disrupt the direct contact between the PS-DVB particles, the smaller the bulk cohesion, as reported in [20]. When it comes to the adhesion with glass ballotini, the surface-modified PS-DVB particles with smaller bulk cohesion are generally supposed to have a weaker adhesion since the additives on such PS-DVB particles should disrupt the direct contact between glass ballotini and PS-DVB particles more efficiently.

However, as the adhesion between the glass ballotini and surface-modified PS-DVB particles increases, the PS-DVB particles between the glass ballotini particles may work as if they are adhesives, causing a rapid increase of the number of the particles involved in the shear motion, \( f(x_s) \cdot n_{tot}(x_s) \), for very small \( x_s \). Modifying the proposed relationship between \( f(x_s) \cdot n_{tot}(x_s) \) and \( x_s \) to a linear function whose gradient is \( 1 - \delta \) \( \cdot \alpha \) after the rapid increase of \( f(x_s) \cdot n_{tot}(x_s) \) at very small \( x_s \), as illustrated by the solid line in Fig. 7b, the function \( f \) can be denoted by the following equation:

\[
f(x_s) = \begin{cases} (1-\delta) \cdot \alpha \cdot \frac{\delta_x - (d_0/d_s) \cdot n_{tot}}{d_0} \cdot n_{tot} \cdot \left( n_x + n_{tot} - (1-\delta) \cdot \frac{n_{tot} - (d_0/d_s) \cdot n_{tot}}{d_0} \right) & (x_s > 0) \\ \frac{\delta_x}{d_0} \cdot n_{tot} & (x_s = 0) \end{cases}
\]

The bulk cohesion of the powder mixtures was then recalculated by substituting Eq. (11) into Eq. (7), instead of Eq. (10).

The coefficients \( A' \) and \( B' \) were again determined as \( A' = \frac{\tau_{x,s}}{(n_{tot} \cdot N_{tot})} \cdot (d_0/d_s) \) and \( B' = \tau_{c,s} \cdot (n_{tot} \cdot N_{tot}) \cdot N_{tot} \cdot N_{tot} \), which can be calculated by substituting \( x_s = 0 \) and 1, respectively. The two parameters, \( C' \) and \( \delta \), were chosen so that Eq. (7) fitted best to the experimental results.

The model calculation shows good agreement with the experimental data when choosing appropriate values for \( C' \) and \( \delta \) for the mixtures with each type of surface-modified PS-DVB powder, as shown in Fig. 9. The values of \( B' \) obtained by calculation, as well as those of \( C' \) and \( \delta \) obtained by fitting, are as listed in Table 5. The value of \( A' \) was fixed at \( 1.0 \times 10^{-12} \) Pa m³.

### 6. Analysis of data based on model

#### 6.1. Meaning of parameters

As mentioned in Section 5, the values of \( A' \), \( B' \), and \( C' \) are the relative measures of the degree of adhesion between ballotini–ballotini,

\( A' = 1.0 \times 10^{-12} \) Pa m³.
The relative measures of the adhesive force between (PS-DVB) and ballotini–(PS-DVB) contacts, respectively. Fig. 10 compares the values of $B^*$ and $C^*$ for each type of binary powder mixture, which validates the assumption mentioned above; namely, that the more surface additives cover the surface of a PS-DVB particle, the less chance the surface-modified PS-DVB particle has of making direct contact, not only with other PS-DVB particles, but also with glass ballotini. The parameter $C^*$ in Eq. (3), representing how easily the binary mixture can be compacted, also has a strong correlation with the parameter $C^*$, as shown in Fig. 11, which implies that $C^*$ also has a correlation with $B^*$. This demonstrates that the packing structure of the binary powder mixtures and the adhesion between the two types of constituent particles are strongly related with each other, similar to the fact that the packing structure of the single component PS-DVB powders is correlated with their bulk cohesion, as seen in Fig. 3.

6.2. Thickness of the incipient shear zone

Since the function $f(x_s)$ is defined as a relative measure of the thickness of the incipient shear zone in the binary powder mixtures, it is possible to analyse the thickness of the incipient shear zone quantitatively in terms of its dependence on $x_s$, as well as effects of the surface-modified PS-DVB. Fig. 12 compares the function $f(x_s)$ for all of the binary powder mixtures, where the lines are the calculated values based on the linear change of $f(x_s) \cdot n_{tot}(x_s)$ and the squares are the recalculated values so that the result of model calculation of Eq. (9) agrees with the experimentally obtained bulk cohesion using the values of parameters $A^*$, $B^*$, $C^*$, and $\delta$ listed in Table 5.

In each case, the function $f(x_s)$ decreases with increasing $x_s$, which seems to reflect the decrease of the average diameter of the powder mixtures. The function $f(x_s)$ increases as the parameter $\delta$ becomes larger, as defined in Eq. (11), so the parameter $\delta$ represents the degree of increase of the incipient shear zone thickness, or the number of particles in the incipient shear zone. In fact, the values of $\delta$ show a good correlation with those of the coefficient $C^*$, as shown in Fig. 13. This fact indicates that the stronger the adhesion between the glass ballotini and PS-DVB particles, the thicker the incipient shear zone becomes, for the same values of $x_s$.

Some values of the function $f$ at very small $x_s$ (i.e. $x_s = -0.002$) obtained from the experimental data (presented in Fig. 12 by dots) show relatively large deviation from the calculated values (lines), in such cases as the mixtures of glass ballotini and PS-DVB(1) or PS-DVB(100). These seem to reflect the fact that the function $f(x_s)$ should converge on $d_1/d_s$ ($= 9.17$) as $x_s$ approaches zero.

*Fig. 9.* Comparison of the model calculation and experimental data for the bulk cohesion of the powder mixtures of glass ballotini and surface-modified PS-DVB powders. Eq. (11) is applied as the function $f(x_s)$ in each case. The solid lines with cross marks represent the results of calculation and the squares are the experimental data.

*Fig. 10.* Relationship found between the coefficients $B^*$ and $C^*$ listed in Table 5. They are the relative measures of the adhesive force between (PS-DVB)–(PS-DVB) and ballotini–(PS-DVB) particles, respectively.

*Fig. 11.* Relationship found between the values of $C^*$, a relative measure of the adhesive force at ballotini–(PS-DVB) contacts, and $G$, a measure of how the powder mixture can be easily compacted.

*Fig. 12.* Function $f(x_s)$, a relative measure of the thickness of the shear zone, as a function of $x_s$. The lines are values calculated from Eq. (11), and the squares are the recalculated values from Eq. (7) using the parameters $A^*$, $B^*$, $C^*$, and $\delta$ listed in Table 5 so that the results agree with the experimentally obtained bulk cohesion.
6.3. Decomposition of total bulk cohesion

Eq. (7) has three terms, \( f \cdot n_{\text{tot}} \cdot A' \cdot N_c(l-l) \), \( f \cdot n_{\text{tot}} \cdot B' \cdot N_c(s-s) \), and \( f \cdot n_{\text{tot}} \cdot C' \cdot N_c(l,s) \), each of which represents the contributions from the cohesion of ballotini–ballotini, (PS-DVB)–(PS-DVB), and ballotini–(PS-DVB) contacts, respectively, to the total bulk cohesion of the powder mixtures. As an example, these three terms calculated using the values of the parameters \( A', B', C', \) and \( \delta \) listed in Table 5 and the function \( f \) which best fits with the experimental data for the mixtures of the glass ballotini and PS-DVB(10) are presented in Fig. 14. As illustrated, the bulk cohesion of the binary powder mixtures is found to be divided into three regions by comparing the values of these three terms. The ballotini–ballotini contacts are dominant in Region I \((x_s < 0.025)\), where their cohesion rapidly decreases and that of ballotini–(PS-DVB) contacts gradually increases, whilst the (PS-DVB)–(PS-DVB) contacts have almost no effect. In Region II \((0.025 < x_s < 0.28)\), the ballotini–(PS-DVB) contacts are the primary contribution to the total bulk cohesion, where the cohesion of ballotini–ballotini contacts approaches zero and that of (PS-DVB)–(PS-DVB) contacts starts increasing with increasing \( x_s \). The cohesion of (PS-DVB)–(PS-DVB) contacts keeps increasing and exceeds that of ballotini–(PS-DVB), and then becomes dominant in Region III \((x_s > 0.28)\).

The same analysis is applicable to all other powder mixtures. By comparing each term separately, it is possible to discuss the effect of the difference of surface-modified PS-DVB powders on the total bulk cohesion in detail. Fig. 15 presents the three terms of the bulk cohesion of each binary powder mixture. The bulk cohesion of the mixtures is
different over the entire range of $x_s$ as shown in Fig. 5(a), which seems to be attributable to the difference in the bulk cohesion of the PS-DVB powders, as mentioned in Section 4. In fact, the cohesion of (PS-DVB)–(PS-DVB) contacts starts increasing once $x_s$ reaches approximately 0.05, and their difference then becomes apparent with increasing $x_s$ as shown in Fig. 15(b). On the other hand, the cohesion of ballotini–ballotini contacts is different below $x_s = -0.05$ (Fig. 15(a)). This reflects the value of $\delta$, which results in the variation of the number of glass ballotini particles involved in the shear motion since the value of $A^i$ is common to all the powder mixtures. The cohesion of ballotini–(PS-DVB) contacts starts increasing once $x_s$ is more than 0.05 (Fig. 15(c)), mainly due to the value of $C^i$, which also affects the change of the total bulk cohesion.

6.4. Relationship with internal friction

By comparing Fig. 5(b) with Fig. 14, it can be found that the linearised friction angle (LFA) at first decreases with the decreasing effect of ballotini–ballotini contacts as well as an increase of the effect of ballotini–(PS-DVB) contacts, and then turns into an increase following the increase of the effect of (PS-DVB)–(PS-DVB) contacts. Therefore, the change of LFA seems to reflect how the contribution of each type of particle contacts changes with the increase of $x_s$ in each powder mixture.

Fig. 16 compares the ratio of the three types of cohesion to the total bulk cohesion, representing the contribution of each type of particle contact to the total bulk flow property. Fig. 16 illustrates that, by using a less cohesive surface-modified PS-DVB powder, both the decrease of the contribution of ballotini–ballotini contacts and increase of that of (PS-DVB)–(PS-DVB) contacts shift in the direction of larger $x_s$, and so does the peak of the contribution of ballotini–(PS-DVB) contacts. As explained in Section 4, the ratio of the surface-modified PS-DVB particles in which the LFA becomes minimum, $x_s(\phi_{\text{lin,min}})$, increases as the bulk cohesion of the surface-modified PS-DVB becomes smaller (Fig. 5(b)), and this corresponds to the shift of the contributions of each type of particle contacts seen in Fig. 16. This fact strongly supports that the suggested model correctly describes the effect of the adhesion between the constituent particles into the bulk flow properties.

Fig. 17 compares $x_s(\phi_{\text{lin,min}})$ and the boundary between Regions II and III defined in Fig. 14, $x_s(1s–ss)$, for all types of the binary powder mixtures, showing the fact that the values of $x_s(\phi_{\text{lin,min}})$ and $x_s(1s–ss)$ have a strong correlation with each other; the values of $x_s(\phi_{\text{lin,min}})$ are always slightly (i.e. 0.04–0.06) smaller than that of $x_s(1s–ss)$.

7. Conclusions

In this study, we have experimentally investigated the bulk flow properties of large-and-small fine binary powder mixtures as a function of the ratio of the component powders, and proposed a semi-empirical model describing their relationship incorporating the contacts between the constituent particles.

First, the incipient flow properties of the binary powder mixtures were evaluated using large-and-small model powder mixtures (of diameter 71.9 and 7.84 µm, respectively). Systematic measurements were conducted using polymer microspheres as smaller particles whose bulk cohesion was controlled by surface additives. The two flow parameters: bulk cohesion, $\tau$, and linearised friction angle (LFA), $\phi_{\text{lin}}$, were obtained from the yield loci obtained by ring shear testing.

The flow properties of the powder mixtures were then compared with their packing structure. The macroscopic structure of the powder mixtures was evaluated in the form of voidage, and then the coordination number of the particles in the mixtures was estimated using Suzuki’s model. With these data, we have developed a semi-empirical model equation in which the total bulk cohesion of the powder mixtures is expressed as a linear superposition of the numbers of the three types of particle contacts involved in the shear motion. An assumption that the number of particles in the incipient shear zone has a linear variation with the volume ratio of the smaller constituent particles (i.e. surface-modified PS-DVB), $x_s$ was made.

The model equation reproduced the experimental data of the bulk cohesion well by choosing appropriate values to the two parameters:
To use less cohesive smaller particles, the value of the bulk cohesion was divided into three regions with increasing contacts: large LFA takes minimum value, stronger the adhesion between the large and small particles, the thicker LFA takes maximum value, and in the incipient shear zone at low contacts, the value of the parameter \(C\) is nearly constant. If the powder is composed of uniform-sized spherical particles, the number of large and small particle contacts per a large particle in the powder can be calculated by considering a powder composed of uniform-sized spherical particles.

As potential further work, the range of validity of the proposed model can be further enhanced by numerical model simulations as some studies have attempted [28–31]. will overcome the interparticle adhesive force, or where the smaller particles’ size is less than approximately 1 \(\mu\)m, and the particles will tend to agglomerate strongly, would be of interest to study.

In summary, the achievements of this study are expected to advance the understanding of the fundamental flow properties of fine powder mixtures. Also, they will give a clear direction of the bulk flow properties of component powders in the design of powder mixtures and realise the better control of the flow behaviour in the products such as EP developers.

Appendix A. Coordination number

Here, a geometric model for calculating the coordination number of the particles in large-and-small binary powder mixtures proposed by Suzuki and co-workers [12–14], which is applied to the analysis of the relationship between flow properties and particle contacts of the binary powder mixtures in this study, is illustrated in detail.

The model takes into account the four different cases of particle contact, i.e.:

Case (i): Large particles in contact with a reference large particle; Case (ii): Small particles in contact with a reference large particle; Case (iii): Large particles in contact with a reference small particle; Case (iv): Small particles in contact with a reference small particle, as illustrated in detail in Refs. [2,13]. The number of particles making contact with a reference particle in cases (i) and (iv) can be obtained by considering a powder composed of uniform-sized spherical particles. In the case of a powder with uniform-sized spheres with diameter \(d\), the relationship between the coordination number \(N_{cu}\) and voidage \(\varepsilon\) of the powder is expressed by the following empirical equation:

\[
N_{cu} = 2.812 \left( \frac{1 - \varepsilon}{b/d} \right)^{1/3},
\]

where \(b\) is a coefficient determined by the voidage \(\varepsilon\), calculated from:

\[
(1-\varepsilon)^{-1/3} = \frac{1 + (b/d)^2}{1 + (b/d) \exp \left( (b/d)^2 \right) - \text{Erfc}(d/b)},
\]

where \(\text{Erfc}(x)\) represents the complementary Gaussian error function. In case (ii), the number of small particles making contact with a reference large particle, \(N_{cu(s-l)}\) is expressed by the following equation:

\[
N_{cu(s-l)} = \frac{N_{cu}}{2} \left( 1 + \frac{d_l}{d_s} \right) \left[ \frac{1}{2} + \frac{d_l}{d_s} - \frac{(d_l/d_s)(d_l/d_s) + 2)^{1/2}}{2} \right],
\]

where \(d_l\) and \(d_s\) are the diameters of large and small powders, respectively. In the same manner, the number of large particles contacting with a reference small particle, case (iii), \(N_{cu(l-s)}\), can be calculated by exchanging the quantities \(d_l\) and \(d_s\) in Eq. (A3).

The coordination number of the large powder, \(N_{c(l)}\), can then be calculated by making the assumption that the number fraction of the contact particles on the reference particle is related to the surface area occupied by the individual contact particle as follows, taking into account cases (i) and (ii):

\[
N_{c(l)} = S_{a,l} N_{cu(l-l)} + S_{a,s} N_{cu(s-l)},
\]

where \(S_{a,l}\) (or \(S_{a,s}\)) is the fractional area ratio of the large (small) powder, defined as the ratio of the total surface area of the large (small) particles in the surface area of all of the particles in the system, with \(S_{a,l} = 1 - S_{a,s}\). The first and second terms in Eq. (A4) represent the number of large–large and large–small particle contacts per a large particle in the powder.
mixture, respectively. The coordination number of the small powder, $N_{c,s}$, can be obtained in the same manner, i.e.:

$$N_{c,s} = S_{c,s}N_{c(s-1)} + S_{a,s}N_{c(s-2)}, \quad (A5)$$

where the first and second terms in Eq. (A5) represent the number of small–large and small–small particle contacts per small particle in the mixture, respectively.

The average coordination number of the total binary powder system, $N_{c,all}$, is the summation of the products of the coordination numbers of each particle, $N_{c,l}$ and $N_{c,s}$, defined in Eqs. (A4) and (A5), and the number ratio of the large (small) powder particles in the total powder system, $S_{c,l}(S_{c,s})$, i.e.:

$$N_{c,all} = S_{c,l}N_{c,l} + S_{c,s}N_{c,s} = S_{c,l}S_{a,l}N_{c(s-1)} + S_{c,l}S_{a,s}N_{c(s-2)} + S_{c,s}S_{a,s}N_{c(s-1)} + S_{c,s}S_{a,l}N_{c(s-2)}. \quad (A6)$$

The first to fourth terms in Eq. (A6) correspond to the average numbers of the particle contacts in cases (i)–(iv): $N_{c(l-1),l}$, $N_{c(s-1),s}$, $N_{c(s-1),l}$, and $N_{c(1-1)}$, respectively.
